Introduction to Machine Learning

Information Theory for Machine Learning

Learning goals

- Minimizing KL is equivalent to maximizing the log-likelihod
- Minimizing KL is equivalent to minimizinig cross-entropy
- Minimizing cross-entropy between modeled and observed probabilities is equivalent to log-loss minimization

KL VS MAXIMUM LIKELIHOOD

Minimizing KL between the true distribution p(x) and approximating model $q(x|\theta)$ is equivalent to maximizing the log-likelihood.

$$egin{aligned} D_{\mathit{KL}}(p\|q_{m{ heta}})) &= \mathbb{E}_{x \sim p} \left[\log rac{p(x)}{q(x|m{ heta})}
ight] \ &= \mathbb{E}_{x \sim p} \log p(x) - \mathbb{E}_{x \sim p} \log q(x|m{ heta}) \end{aligned}$$

The first term above does not depend on θ . Therefore,

$$rg \min_{m{ heta}} D_{\mathit{KL}}(m{p} \| q_{m{ heta}}) = rg \min_{m{ heta}} - \mathbb{E}_{x \sim p} \log q(x | m{ heta})$$

$$= rg \max_{m{ heta}} \mathbb{E}_{x \sim p} \log q(x | m{ heta})$$

For a finite dataset of n samples from p, this is approximated as

$$\operatorname{arg\,max}_{\boldsymbol{\theta}} \mathbb{E}_{\boldsymbol{x} \sim \boldsymbol{\rho}} \log q(\boldsymbol{x}|\boldsymbol{\theta}) \approx \operatorname{arg\,max}_{\boldsymbol{\theta}} \frac{1}{n} \sum_{i=1}^{n} \log q(\mathbf{x}^{(i)}|\boldsymbol{\theta}).$$

KL VS CROSS-ENTROPY

From this here we can actually see much more:

$$rg\min_{m{ heta}} D_{\mathit{KL}}(p\|q_{m{ heta}}) = rg\min_{m{ heta}} - \mathbb{E}_{m{x} \sim m{p}} \log q(m{x}|m{ heta}) = H_{q_{m{ heta}}}(p)$$

- So minimizing with respect to KL is the same as minimizing with respect to cross-entropy!
- That implies minimizing with respect to cross-entropy is the same as maximum likelihood!
- Remember, how we only characterized cross-entropy through source coding / bits? We could now motivate cross-entropy as the "relevant" term that you have to minimize, when you minimize KL after you drop $\mathbb{E}_p \log p(x)$, which is simply the entropy H(p)!
- Or we could say: Cross-entropy between p and q is simply the expected negative log-likelihood of q, when our data comes from p!

CROSS-ENTROPY VS. LOG-LOSS

- Consider a multi-class classification task with dataset $\mathcal{D} = ((\mathbf{x}^{(1)}, y^{(1)}), \dots, (\mathbf{x}^{(n)}, y^{(n)})).$
- For g classes, each $y^{(i)}$ can be one-hot-encoded as a vector $d^{(i)}$ of length g. $d^{(i)}$ can be interpreted as a categorical distribution which puts all its probability mass on the true label $y^{(i)}$ of $\mathbf{x}^{(i)}$.
- $\pi(\mathbf{x}^{(i)}|\boldsymbol{\theta})$ is the probability output vector of the model, and also a categorical distribution over the classes.

CROSS-ENTROPY VS. LOG-LOSS

To train the model, we minimize KL between $d^{(i)}$ and $\pi(\mathbf{x}^{(i)}|\boldsymbol{\theta})$:

$$\arg\min_{\boldsymbol{\theta}} \sum_{i=1}^{n} D_{KL}(\boldsymbol{d}^{(i)} \| \pi(\mathbf{x}^{(i)} | \boldsymbol{\theta})) = \arg\min_{\boldsymbol{\theta}} \sum_{i=1}^{n} H_{\pi(\mathbf{x}^{(i)} | \boldsymbol{\theta})}(\boldsymbol{d}^{(i)})$$

We see that this is equivalent to log-loss risk minimization!

$$R = \sum_{i=1}^{n} H_{\pi_k(\mathbf{x}^{(i)}|\boldsymbol{\theta})}(\boldsymbol{d}^{(i)})$$

$$= \sum_{i=1}^{n} \left(-\sum_{k} d_k^{(i)} \log \pi_k(\mathbf{x}^{(i)}|\boldsymbol{\theta}) \right)$$

$$= \sum_{i=1}^{n} \left(-\sum_{k=1}^{g} [y^{(i)} = k] \log \pi_k(\mathbf{x}^{(i)}|\boldsymbol{\theta}) \right)$$

$$= \sum_{i=1}^{n} (-\log \pi_{y^{(i)}}(\mathbf{x}^{(i)}|\boldsymbol{\theta}))$$

CROSS-ENTROPY VS. BERNOULLI LOSS

For completeness sake:

Let us use the Bernoulli loss for binary classification:

$$L(y, \pi(\mathbf{x})) = -y \ln(\pi(\mathbf{x})) - (1-y) \ln(1-\pi(\mathbf{x}))$$

If p represents a Ber(y) distribution (so deterministic, where the true label receives probability mass 1) and we also interpret $\pi(\mathbf{x})$ as a Bernoulli distribution Ber($\pi(\mathbf{x})$), the Bernoulli loss $L(y, \pi(\mathbf{x}))$ is the cross-entropy $H_{\pi(\mathbf{x})}(p)$.

ENTROPY AS PREDICTION LOSS

Assume log-loss for a situation where you only model with a constant probability vector π . We know the optimal model under that loss:

$$\pi_k = \frac{n_k}{n} = \frac{\sum_{i=1}^n [y^{(i)} = 1]}{n}$$

What is the (average) risk of that minimal constant model?

ENTROPY AS PREDICTION LOSS

$$\mathcal{R} = \frac{1}{n} \sum_{i=1}^{n} \left(-\sum_{k=1}^{g} [y^{(i)} = k] \log \pi_k \right)$$

$$= -\frac{1}{n} \sum_{k=1}^{g} \sum_{i=1}^{n} [y^{(i)} = k] \log \pi_k$$

$$= -\sum_{k=1}^{g} \frac{n_k}{n} \log \pi_k$$

$$= -\sum_{k=1}^{g} \pi_k \log \pi_k = H(\pi)$$

So entropy is the (average) risk of the optimal "observed class frequency" model under log-loss!
